Abstract. Studies have shown that each person is more inclined to enjoy a group activity when 1) she is interested in the activity, and 2) many friends with the same interest join it as well. Nevertheless, even with the interest and social tightness information available in online social networks, nowadays many social group activities still need to be coordinated manually. In this paper, therefore, we first formulate a new problem, named Participant Selection for Group Activity (PSGA), to decide the group size and select proper participants so that the sum of personal interests and social tightness of the participants in the group is maximized, while the activity cost is also carefully examined. To solve the problem, we design a new randomized algorithm, named Budget-Aware Randomized Group Selection (BARGS), to optimally allocate the computation budgets for effective selection of the group size and participants, and we prove that BARGS can acquire the solution with a guaranteed performance bound. The proposed algorithm was implemented in Facebook, and experimental results demonstrate that social groups generated by the proposed algorithm significantly outperform the baseline solutions.

1 Introduction

Studies have shown that two important factors are usually involved in a person's decision to join a social group activity: (1) interest in the activity topic or content, and (2) social tightness with other attendees [5, 8]. For example, if a person who appreciates jazz music has complimentary tickets for a jazz concert in Rose Theatre, she is inclined to invite her friends or friends of friends who are also jazzists. However, even the information on the two factors is now available online, the attendees of most group activities still need to be selected manually, and the process will be tedious and time-consuming, especially for a large social activity, given the complicated social link structure and the diverse interests of potential attendees.

Recent studies have explored community detection, graph clustering and graph partitioning to identify groups of nodes mostly based on the graph structure [1]. The quality of an obtained community is usually measured according to its internal structure, together with its external connectivity to the rest of

the nodes in the graph [7]. Those approaches are not designed for activity planning because it does not consider the interests of individual users along with the cost of holding an activity with different numbers of participants. An event which attracts too few or too many attendees will result in unacceptable loss for the planner. Therefore, it is important to incorporate the preference of each potential participant, their social connectivity, and the activity cost during the planning of an activity.

With this objective in mind, a new optimization problem is formulated, named *Participant Selection for Group Activity (PSGA)*. The problem is given a cost function related to the group size and a social graph G , where each node represents a potential attendee and is associated with an interest score that describes the individual level of interest. Each edge has a social tightness score corresponding to the mutual familiarity between the two persons. Since each participant is more inclined to enjoy the activity when 1) she is interested in the activity, and 2) many friends with the same interest join as well, the *preference* of a node v_i for the activity can be represented by the sum of its interest score and social tightness scores of the edges connecting to other participants, while the *group preference* is sum of the total interest scores of all participants and the social tightness scores of the edges connecting to any two participants. Moreover, the *group utility* here is represented by the group preference subtracted by the *activity cost* (ex. the expense in food and siting), which is usually correlated to the number of participants.⁴ The objective of PSGA is to determine the best group size and select proper participants, so that the group utility is maximized. In addition, the induced graph of the set F of selected participants is desired to be a connected component, so that each attendee is possible to become acquainted with another attendee according to a social path⁵.

One possible approach to solving PSGA is to examine every possible combination on every group size. However, this enumeration approach of group size k requires the evaluation of C_k^n candidate groups, where n is the number of nodes in G . Therefore, the number of group size and attendee combinations is $O(2^n)$, and it thereby is not feasible in practical cases. Another approach is to incrementally construct the group using a greedy algorithm that iteratively tries each group size and sequentially chooses an attendee that leads to the largest increment in group utility at each iteration. However, greedy algorithms are inclined to be trapped in local optimal solutions. To avoid being trapped in local optimal solutions, randomized algorithms have been proposed as a simple but effective strategy to solve problems with large instances [12].

A simple randomized algorithm is to randomly choose multiple start nodes initially. Each start node is considered as a partial solution, and a node neigh-

⁴ Different weighted coefficients can be assigned to the group utility and activity cost according to the corresponding scenario.

⁵ For some group activities, it is not necessary to ensure that F leads to a connected subgraph, and those scenarios can be handled by adding a virtual node v connecting to every other node in G , and choosing v in F for PSGA always creates a connected subgraph in $G \cup \{v\}$, but F may not be a connected subgraph in G .

boring the partial solution is randomly chosen and added to the partial solution at each iteration later. Nevertheless, this simple strategy has three disadvantages. Firstly, a start node that has the potential to generate final solutions with high group utility does not receive sufficient computational resources for randomization in the following iterations. More specifically, each start node in the randomized algorithm is expanded to only one final solution. Thus, a good start node will usually fail to generate a solution with high group utility since it only has one chance to randomly generate a final solution. The second disadvantage is that the expansion of the partial solution does not differentiate the selection of the neighboring nodes. Each neighboring node is treated equally and chosen uniformly at random for each iteration. Even this issue can be partially resolved by assigning the selection probability to each neighboring node according to its interest score and the social tightness of incident edges, this assignment will lead to the greedy selection of neighbors and thus tends to be trapped in local optimal solutions as well. The third disadvantage is that the linear scanning of different group sizes is not computationally tractable for real scenarios as an online social network contains an enormous number of nodes.

Keeping the above observations in mind, we propose a randomized algorithm, called *Budget-Aware Randomized Group Selection (BARGS)*, to effectively select the start nodes, expand the partial solutions, and estimate the suitable group size. The computational budget represents the target number of random solutions. Specifically, *BARGS* first selects a group size limit k_{max} in accordance with the cost function⁶. Afterward, m start nodes are selected, and neighboring nodes are properly added to expand the partial solution iteratively, until k_{max} nodes are included, while the group size corresponding to the largest group utility is acquired finally. Each start node in *BARGS* is expanded to multiple final solutions according to the assigned budget. To properly invest the computational budgets, each stage of *BARGS* invests more budgets on the start nodes and group sizes that are more inclined to generate good final solutions, according to the sampled results from the previous stages. Moreover, the node selection probability is adaptively assigned in each stage by exploiting the cross entropy method. In this paper, we show that our allocation of computation budgets is the optimal strategy, and prove that the solution acquired by *BARGS* has a guaranteed performance bound.

The rest of this paper is organized as follows. Section 2 formulates PSGA and surveys related works. Sections 3 explains *BARGS* and derives the performance bound. User study and experimental results are presented in Section 4, and we conclude this paper in Section 5.

⁶ For instance, if the largest capacity of available stadiums for a football game is 20,000, k_{max} is set as 20,000.

2 Preliminary

2.1 Problem Definition

Given a social network $G = (V, E)$, where each vertex $v_i \in V$ and each edge $e_{i,j} \in E$ are associated with an interest score η_i and a social tightness score $\tau_{i,j}$ respectively, we study a new optimization problem for finding a set F of vertices which maximizes the *group utility* $U(F)$, i.e.,

$$U(F) = \sum_{v_i \in F} (\eta_i + \sum_{v_j \in F: e_{i,j} \in E} \pi_{i,j}) - \beta C(|F|), \quad (1)$$

where F with $|F| \leq k_{max}$ is a connected subgraph in G to encourage each attendee to be acquainted with another attendee with at least one social path in F , C is a non-negative activity cost function based on the number of attendees, and β is a weighted coefficient between the preference and cost. For each node i , let $\eta_i + \sum_{v_j \in F: e_{i,j} \in E} \pi_{i,j}$ denote the *preference* of node i on the social group activity. PSGA is very challenging due to the tradeoff between interest, social tightness, and the cost function, while the constraint assuring that F is connected also complicates this problem because it is no longer able to arbitrarily choose any nodes from G . Indeed, we show that PSGA is NP-hard..

Theorem 1. *PSGA is NP-Hard.*

Proof. We prove that PSGA is NP-hard with the reduction from DkS problem [6]. Given a graph $G_D = (V_D, E_D)$, DkS finds a subgraph with k nodes F_D to maximize the density of the subgraph. In other words, the purpose of DkS is to maximize the number of edges $E(F_D)$ in the subgraph induced by the selected nodes.

For each instance of DkS, we construct an instance for PSGA by letting $G = G_D$ and $k_{max} = \infty$, where η_i of each node $v_i \in V$ is set as 0, $\tau_{i,j}$ of each edge $e_{i,j} \in E$ is assigned as 1, and $\beta = 1$, $C(i) = 0$ for $i = k$ and $C(i) = \infty$ for $i \neq k$. Therefore, PSGA will always select k nodes to avoid creating a negative objective value. We first prove the sufficient condition. For each instance of DkS with solution node set F_D , we let $F = F_D$. If the number of edges $E(F_D)$ in the subgraph of DkS is δ , the preference of PSGA $W(F)$ is also δ because $F = F_D$ and the optimal group size must be k . We then prove the necessary condition. For each instance of PSGA with F , we select the same nodes for F_D , and the number of edges $E(F_D)$ must be maximized since the node number in the solution of PSGA is k . The theorem follows. $\square$

2.2 Related Works

A recent line of study has been proposed to find cohesive subgroups in social networks with different criteria, such as cliques, n -clubs, k -core, and k -plex. Sarıyüce et al. [14] proposed an efficient parallel algorithm to find a k -core subgraph, where every vertex is connected to at least k vertices in the subgraph.

Xiang et al. [16] proposed a branch-and-bound algorithm to acquire all maximal cliques that cannot be pruned during the search tree optimization. Moreover, finding the maximum k -plexes was comprehensively discussed in [11]. On the other hand, community detection and graph clustering have been exploited to identify the subgraphs with the desired structures [1]. The quality of a community is measured according to the structure inside the community and the structure between the community and the rest of the nodes in the graph, such as the density of local edges, deviance from a random null model, and conductance [7]. Nevertheless, the above models did not examine the interest score of each user and the social tightness scores between users, which have been regarded as crucial factors for social group activities. Moreover, the activity cost for the group is not incorporated during the evaluation.

In addition to dense subgraphs, social groups with different characteristics have been explored for varied practical applications. Expert team formation in social networks has attracted extensive research interest. The problem of constructing an expert team is to find a set of people possessing the required skills, while the communication cost among the chosen friends is minimized to optimize the rapport among the team members to ensure efficient operation. Communication costs can be represented by the graph diameter, the size of the minimum spanning tree, and the total length of the shortest paths [9]. By contrast, minimizing the total spatial distance with R-Tree from the group with a given number of nodes to the rally point is also studied [17]. Nevertheless, this paper focuses on a different scenario that aims at identifying a group with the most suitable size according to the activity cost, while those selected participants also share the common interest and high social tightness.

3 Algorithm Design for PSGA

To solve PSGA, a baseline approach is to incrementally constructing the solution by sequentially choosing and adding a neighbor node that leads to the largest increment in the group preference until k_{max} people are selected. Afterward, we derive the group utility for each k by incorporating the activity cost, $1 \leq k \leq k_{max}$, and extract the group size k^* with the maximum group utility.

The greedy algorithm, despite the simplicity, the search space of the greedy algorithm is limited and thus tends to be trapped in a local optimal solution, because only a single sequence of solutions is explored. To address the above issues, this paper proposes a randomized algorithm *BARGS* to randomly choose m start nodes⁷. *BARGS* leverages the notion of Optimal Computing Budget Allocation (OCBA) [3] to systematically generate the solutions from each start node, where the start nodes with more potential to generate the final solutions with large group utility will be allocated with more budgets (i.e., expanded to more final solutions). In addition, since each start nodes can generate the final solutions with different group sizes, the size with larger group utility will be

⁷ The impact of m will be studied in Section 4.

associated with more budgets as well (i.e., generated more times). Specifically, *BARGS* includes the following two phases.

1) *Selection and Evaluation of Start Nodes and Group Sizes*: This phase first selects m start nodes according to the summation of the interest scores and social tightness scores of incident edges. Each start node acts as a seed to be expanded to a few final solutions. At each iteration, a partial solution, which consists of only a start node at the first iteration or a connected set of nodes at any iteration afterward, is expanded by randomly selecting a node neighboring to the partial solution, until $k_{\max}$ nodes are included. The group utility of each final solution is evaluated to optimally allocate different computational budgets to different start nodes and different group sizes in the next phases.

2) *Allocation of Computational Budgets*: This phase is divided into r stages⁸, while each stage shares the same total computational budget. In the first stage, the computational budget allocated to each start node is determined by the sampled group utility in the first phase. In each stage afterward, the computational budget allocated to each start node is adjusted by the sampled results in the previous stages. Note that each node can generate different numbers of final solutions with different group sizes. The sizes with small group utility sampled in the previous stages will be associated with smaller computational budgets in the current stage. Therefore, if the activity cost is a convex cost function, the cost increases more significantly as the group size grows, and *BARGS* tends to allocate smaller computational budgets and thus generate fewer final solutions with large group sizes.

During the expansion of the partial solutions, we differentiate the probability to select each node neighboring to a partial solution. One intuitive way is to associate each neighboring node with a different probability according to the sum of the interest score and social tightness score on the incident edge. Nevertheless, this assignment is similar to the greedy algorithm as it limits the scope to only the local information associated with each node, making it difficult to generate a final solution with large group utility. By contrast, *BARGS* exploits the cross entropy method [13] according to sampled results in the previous stages in order to optimally assign a probability to the edge incident to a neighboring node.

The detailed pseudocode is presented in Algorithm 1. In the following, we first present how to optimally allocate the computational budgets to different start nodes and different group sizes. Afterward, we exploit the cross entropy method to differentiate the neighbor selection during the expansion of the partial solutions. Finally, we derive the approximation ratio of the proposed algorithm.

Allocation of Computational Budgets Similar to the baseline greedy algorithm, allocating more computational budgets to a start node v_i with larger group utility (i.e., $\eta_i + \sum_{v_j \in F: e_{i,j} \in E} \pi_{i,j}$) examines only the local information and thus is difficult to generate the solution with large group utility. Therefore,

⁸ The detailed settings of the parameters of the algorithm, such as m , r , α , and β are presented in the next section

to optimally allocate the computational budgets for each start node and size, we first define the solution quality as follows.

Definition 1. *The solution quality, denoted by Q , is defined as the maximum group utility of the solution generated from the m start nodes among all sizes.*

For each stage t of phase 2 in *BARGS*, let $N_{i,k,t}$ denote the computational budgets allocated to the start node v_i with size k in the t -th stage. In the following, we first derive the optimal ratio of the computational budgets allocated to any two start nodes v_i and v_j with size k and l , respectively. Let two random variables $Q_{i,k}$ and $Q_{i,k}^*$ denote the sampled group utility of any solution and the maximal sampled group utility of a solution for start node v_i with size k , respectively. If the activity cost is not considered, according to the central limit theorem, $Q_{i,k}$ follows the normal distribution when $N_{i,k}$ is large, and it can be approximated by the uniform distribution in $[c_{i,k}, d_{i,k}]$ as analyzed in OCBA [3], where $c_{i,k}$ and $d_{i,k}$ denote the minimum and maximum sampled group utility in the previous stages, respectively. On the other hand, when the activity cost is considered, the cumulative distribution function is shifted by $C(k)$, and it still follows the same distribution. Therefore, we have the following lemma.

Lemma 1. *The probability that the solution generated from the start node v_i with size k is better than the solution generated from the start node v_j with size l , i.e., $P(Q_{i,k}^* \leq Q_{j,l}^*)$, is as follows.*

$$P(Q_{i,k}^* \leq Q_{j,l}^*) \leq \begin{cases} 0 & \text{if } d_{j,l} \leq c_{i,k}. \\ \frac{1}{2} \left(\frac{d_{j,l} - c_{i,k}}{d_{i,k} - c_{i,k}} \right)^{N_{i,k}} & \text{if } d_{j,l} \geq c_{i,k} \\ 1 & \text{if } d_{i,k} \leq c_{j,l} \end{cases} \quad (2)$$

Proof. The cumulative distribution function of $Q_{i,k}$ is

$$P_{Q_{i,k}}(x) = \begin{cases} 0 & \text{if } x \leq c_{i,k}. \\ \frac{x - c_{i,k}}{d_{i,k} - c_{i,k}} & \text{if } c_{i,k} \leq x \leq d_{i,k}. \\ 1 & \text{otherwise.} \end{cases}$$

After incorporating the operation cost function $C(|F|)$ with $|F| = k$, the cumulative distribution function of $Q_{i,k}$ is

$$P_{Q_{i,k}}(x) = \begin{cases} 0 & \text{if } x \leq c_{i,k} - \beta C(k). \\ \frac{x - c_{i,k}}{d_{i,k} - c_{i,k}} & \text{if } c_{i,k} - \beta C(k) \leq x \leq d_{i,k} - \beta C(k). \\ 1 & \text{otherwise.} \end{cases} \quad (3)$$

Therefore, for the maximal value $Q_{i,k}^*$,

$$p_{Q_{i,k}^*}(x) = N_{i,k} P_{Q_{i,k}}(x)^{N_{i,k}-1} p_{Q_{i,k}}(x),$$

$$P_{Q_{i,k}^*}(x) = P_{Q_{i,k}}(x)^{N_{i,k}}.$$

From Eq. 3, the cumulative distribution function is shifted by $C(k)$ when we incorporate the operation cost, and it thus still follows the same distribution. Assume that $d_{j,l} > c_{i,k}$, the probability that the solution generated from the start node v_i with size k is better than the solution generated from the start node v_j with size l , i.e., $P(Q_{i,k}^* \leq Q_{j,l}^*)$, can be derived according to [15] as follows.

$$P(Q_{i,k}^* \leq Q_{j,l}^*) \leq \begin{cases} 0 & \text{if } d_{j,l} \leq c_{i,k}. \\ \frac{1}{2} \left(\frac{d_{j,l} - c_{i,k}}{d_{i,k} - c_{i,k}} \right)^{N_{i,k}} & \text{if } d_{j,l} \geq c_{i,k} \\ 1 & \text{if } d_{i,k} \leq c_{j,l} \end{cases}$$

The Lemma follows. $\square$

Let v_b and k_b^* denote the best start node and best activity size for v_b , respectively. With Lemma 1, *BARGS* in each stage allocates the computational budgets to different start nodes as follows.

$$\frac{N_{i,t}}{N_{j,t}} = \frac{P(Q = Q_i^*)}{P(Q = Q_j^*)}, \quad (4)$$

where $P(Q = Q_i^*) = \sum_k P(Q_{i,k}^* \geq Q_{b,k_b^*}^*)$, and the ratio of the computational budget allocation is optimal in OCBA [3], which implies that any other allocation generates a smaller Q . Note that if the allocated computational budgets for a start node is 0 in the t -th stage, we prune off the start node in the any stage afterward. After deriving the computational budget $N_{i,t}$ for each start node v_i , we distribute the budgets to the solutions with different group sizes. Let $N_{i,k,t}$ denote the number of solutions with group size k from the start node v_i .

$$N_{i,k,t} = N_{i,t} \frac{P(Q_{i,k}^* \geq Q_{b,k_b^*}^*)}{\sum_k P(Q_{i,k}^* \geq Q_{b,k_b^*}^*)}. \quad (5)$$

It is worth noting that when we generate a solution with size k , the solutions from size 1 to size $k-1$ are also generated as well. Therefore, to avoid generating an excess number the solutions with small group sizes, it is necessary to relocate the computation budgets. Let $\hat{N}_{i,k,t}$ denote the reallocated budget of start node v_i with size k in t -th stage. *BARGS* reallocates the computational budgets from size $k-1$ as follows.

$$\hat{N}_{i,k,t} = \max(0, N_{i,k,t} - \sum_{l>k} \hat{N}_{i,l,t}). \quad (6)$$

Specifically, after deriving $N_{i,k,t}$ with Eq. 5, *BARGS* derives $\hat{N}_{i,k,t}$ from $k = k_{max}$ to 1. Initially, $\hat{N}_{i,k_{max},t} = N_{i,k_{max},t}$. Afterward, for $k = k_{max} - 1$, if $N_{i,k_{max}-1,t}$ is

Fig. 1. Illustrative example of BARGS

equal to $N_{i,k_{max},t}$, it is not necessary to generate additional solutions with size $k_{max} - 1$ since they have been created during the generation of the solutions with size k_{max} . In this case, $\hat{N}_{i,k_{max}-1,t}$ is 0. Otherwise, $BARGS$ sets $\hat{N}_{i,k_{max}-1,t} = N_{i,k_{max}-1,t} - N_{i,k_{max},t}$. The above process repeats until $k = 1$. Since the number of solutions with size k is still $N_{i,k,t}$, the computational budget allocation is still optimal as shown in Eq. 4.

Neighboring Node Differentiation To effectively differentiate neighbor selection, $BARGS$ takes advantage of the cross entropy method [13] to achieve importance sampling by adaptively assigning a different probability to each neighboring node from the sampled results in previous stages. Take start node v_i with size k as an example, after collecting $N_{i,k,1}$ samples $X_{i,k,1}, X_{i,k,2}, \dots, X_{i,k,q}, \dots, X_{i,k,N_{i,k,1}}$ generated from start node v_i , $BARGS$ calculates the total group utility $U(X_{i,k,q})$ for each sample and sorts them in the descending order, $U_{(1)} \geq \dots \geq U_{(N_{i,k,1})}$. Let $\gamma_{i,k,1}$ denotes the group utility of the top- ρ performance sample, i.e. $\gamma_{i,k,1} = U_{(\lceil \rho N_{i,k,1} \rceil)}$. With those sampled results, we set the selection probability $p_{i,k,t+1,j}$ of every node v_j in iteration $t + 1$ from the partial solution expanded from node v_i by fitting the distribution of top- ρ performance samples as follows.

Definition 2. A Bernoulli sample vector, denoted as $X_{i,k,q} = \langle x_{i,k,q,1}, \dots, x_{i,k,q,j}, \dots, x_{i,k,q,n} \rangle$, is defined to be the q -th sample vector from start node v_i , where $x_{i,k,q,j}$ is 1 if node v_j is selected in the q -th sample and 0 otherwise.

$$p_{i,k,t+1,j} = \frac{\sum_{q=1}^{N_{i,k,t}} I_{\{U(X_{i,k,q}) \geq \gamma_{i,k,t}\}} x_{i,k,q,j}}{\sum_{q=1}^{N_{i,k,t}} I_{\{U(X_{i,k,q}) \geq \gamma_{i,k,t}\}}}, \quad (7)$$

where $I_{\{U(X_{i,k,q}) \geq \gamma_{i,k,t}\}}$ is 1 if the group utility of sample $X_{i,k,q}$ exceeds a threshold $\gamma_{i,k,t} \in \mathbb{R}$, and 0 otherwise. Intuitively, the neighbor that tends to generate a better solution will be assigned a higher selection probability. As shown in [13], the above probability assignment scheme has been proved to be optimal from the perspective of cross entropy. Eq. 7 minimizes the Kullback-Leibler cross entropy (KL) distance between node selection probability $\vec{p}_{i,k,t+1}$ and the distribution of top- ρ performance samples, such that the performance of random samples in $(t + 1)$ -th stage is guaranteed to be closest to the top- ρ performance samples in t -th stage.

Example 1. Figure 1 presents an illustrative example with a social network of size 6. For the greedy algorithm, v_5 is first selected since its interest score is the

maximum among all nodes, i.e., 0.7. Afterward, node v_6 is extracted with total preference of $0.7 + 0.5 + 0.6 = 1.8$. v_4 , instead of v_2 or v_3 , is chosen because it generates the largest increment of preference, i.e., 0.7, and leads to a group with total preference of 2.5. After v_1 is further selected with the increment of 1.1, v_2 is selected with total preference of 4.9. Finally, v_3 is selected with total preference of 5.6. Assume that the weighting β between preference and cost function is 0.01^9 , the greedy algorithm scans each size to obtain the best size, i.e., calculating the maximum among $0.7 - 0.01 \cdot 400$, $1.8 - 0.01 \cdot 300$, $2.5 - 0.01 \cdot 200$, $3.6 - 0.01 \cdot 350$, $4.9 - 0.01 \cdot 500$, and $5.6 - 0.01 \cdot 650$, and obtains the best size is 3 with group utility of 0.5. In this simple example, the above algorithm is not able to find the optimal solution since it facilitates the selection of nodes only suitable at the corresponding iterations.

We also take Figure 1 as an illustrative example for *BARGS* with $k_{max} = 4$. Phase 1 first chooses $\lceil n/k_{max} \rceil = 2$ start nodes by summing up the topic interest score and the social tightness scores for every node. Therefore, v_2 with $0.6 + 0.7 + 0.6 + 0.9 - 0.6 = 2.2$ and v_6 with $0.6 + 0.5 + 0.7 = 1.8$ are selected. Next, let $T = 20$, $P_b = 0.7$ and $\alpha = 0.9$ in this example, and the number of stages is thus $r \leq \frac{Tk_{max} \ln \alpha}{n \ln(\frac{2(1-P_b)}{m-1})} = \frac{20 \cdot 4 \ln 0.9}{6 \ln(0.6)} \approx 2$. Each start node generates 5 samples in the first stage. The intermediate solution obtained so far is denoted as V_S , and the candidate attendees extracted so far is denoted as V_A . Therefore, by selecting v_2 as a start node, the total group utility of $V_S = \{v_2\}$ is $0.6 - 0.01 \cdot 400 = -3.4$, and $V_A = \{v_1, v_3, v_4, v_5\}$. Since the node selection probability is homogeneous in the first stage, we randomly select v_1 from V_A to expand V_S . Now the total group utility of $V_S = \{v_1, v_2\}$ is $U(V_S) = 0.6 + 0.7 + 0.6 - 0.01 \cdot 300 = -1.1$, and $V_A = \{v_3, v_4, v_5\}$. The process of expanding V_S continues until the cardinality of V_S reaches $k_{max} = 4$, e.g. v_5 and then v_3 . Afterward, we record the first sample result $X_{2,2,1} = \langle 1, 1, 0, 0, 0 \rangle$ with the total group utility of -1.1 , the worst result of v_2 with size 2 ($c_{2,2} = -1.1$), and the best result of v_2 with size 2 ($d_{2,2} = -1.1$). Similarly, $X_{2,3,1} = \langle 1, 1, 0, 0, 1, 0 \rangle$ with the total group utility of -1 and $X_{2,4,1} = \langle 1, 1, 1, 0, 1, 0 \rangle$ with the total group utility of 0.7 . The second sampled results from start node v_2 are $\{v_2, v_3, v_4, v_1\}$. Therefore, $X_{2,2,2} = \langle 0, 1, 1, 0, 0, 0 \rangle$ with the total group utility of -1.4 , $X_{2,3,2} = \langle 0, 1, 1, 1, 0, 0 \rangle$ with the total group utility of 0.8 , $X_{2,4,2} = \langle 1, 1, 1, 1, 0, 0 \rangle$ with the total group utility of 1.2 . Afterward, the worst and the best results of v_2 are updated to $c_{2,2} = -1.4$, $d_{2,2} = -1.1$, $c_{2,3} = -1$, $d_{2,3} = 0.8$, $c_{2,4} = 0.7$, and $d_{2,4} = 1.2$. After drawing 3 more samples from node v_2 , we repeat the above process for start node v_6 with 5 samples. The results are summarized on the right of Figure 1.

To allocate the computational budgets for the second stage, i.e., $r = 2$, we first find the allocation ratio $N_{2,2} : N_{6,2} = \frac{1}{2}((\frac{-1.1 - (-1.3)}{1.6 - (-1.3)})^5 + 1 + (\frac{1.1 - (-1.3)}{1.6 - (-1.3)})^5) : \frac{1}{2}((\frac{-1.2 - (-1.3)}{1.6 - (-1.3)})^5 + (\frac{0.8 - (-1.3)}{1.6 - (-1.3)})^5 + (\frac{0.6 - (-1.3)}{1.6 - (-1.3)})^5) = 1.39 : 0.32$. Therefore, the allocated computational budgets for start nodes v_2 and v_6 are $\frac{10 \cdot 1.39}{1.71} \approx 8$ and $\frac{10 \cdot 0.32}{1.71} \approx 2$, respectively. $\hat{N}_{2,2,2}$, $\hat{N}_{2,3,2}$, and $\hat{N}_{2,4,2}$ approximate 0, $\frac{8}{1.388} \approx 6$, and $\frac{8 \cdot 0.388}{1.388} \approx 2$, respectively. *BARGS* reallocates the computational budgets by

⁹ The parameter setting of α will be introduced in more details in the next section.

$\hat{N}_{2,3,2} = N_{2,3,2} - \hat{N}_{2,4,2} = 6$. Afterward, we update the node selection probability. Take the node selection probability for start node v_2 with size 3 in the second stage for node v_1 as an example, i.e., $p_{2,3,2,1}$. Given $\rho = 0.6$, i.e., *BARGS* selects top-3 performance samples, if v_1 is selected 2 times in top-3 performance samples, $p_{2,3,2,1}$ is set as $\frac{2}{3}$. The process for v_6 is similar and thus omitted here due to the space constraint. After the second stage, the optimal solution is $\{v_1, v_2, v_4\}$ with maximum group utility of 1.6, which is better than the group utility generated by the greedy algorithm, i.e., 0.5.

Theoretical Results The following theorem first analyzes the probability $P(Q = Q_{b,k_b^*}^*)$ that v_b , as decided according to the samples in the previous stages, is actually the start node that generates the maximal group utility with optimal size k_b^* . Let α denote the closeness ratio between the maximum of the start node with the maximal group utility and the maximum of other start nodes or with different sizes, i.e., $\alpha = (d_{a,k_a^*} - c_{b,k_b^*}) / (d_{b,k_b^*} - c_{b,k_b^*})$, where v_a generates the maximal group utility among other start nodes. Therefore, in addition to 0 and 1, α is allowed to be any other value from 0 to 1.

Theorem 2. *For PSGA with parameter (m, T, k_{max}) , where m is the number of start nodes, T is the total computational budgets, and k_{max} is the group size limit, the probability $P(Q = Q_{b,k_b^*}^*)$ that v_b selected according to the previous stages is actually the start node that generates the optimal solution with optimal size k_b^* is at least $1 - \frac{1}{2}(k_{max} + m - 2)\alpha^{\frac{T}{rmk_{max}}}$.*

Proof. According to the Bonferroni inequality, $p\{\cap_{i=1}^m (Y_i < 0)\} \geq 1 - \sum_{i=1}^m [1 - p(Y_i < 0)]$. In our case, Y_i is replaced by $Q_{i,k_i^*}^* - Q_{b,k_b^*}^*$ to acquire a lower bound for the probability that v_b enjoys the maximal group utility with optimal size k_b^* . Therefore, by using Equation 2,

$$\begin{aligned}
& P(Q = Q_{b,k_b^*}^*) \\
&= p\{\cap_{l=1, l \neq k_b^*}^{k_{max}} (Q_{b,l}^* - Q_{b,k_b^*}^*) \leq 0\} \cdot \\
&\quad p\{\cap_{i=1, i \neq b}^m (Q_{i,k_i^*}^* - Q_{b,k_b^*}^*) \leq 0\} \\
&\geq (1 - \sum_{l=1, l \neq k_b^*}^{k_{max}} [1 - p(Q_{b,k_l^*}^* - Q_{b,k_b^*}^* \leq 0)]) \cdot \\
&\quad (1 - \sum_{i=1, i \neq b}^m [1 - p(Q_{i,k_i^*}^* - Q_{b,k_b^*}^* \leq 0)]) \\
&\geq (1 - \frac{1}{2} \sum_{l=1, l \neq k_b^*}^{k_{max}} (\frac{d_{b,l} - c_{b,k_b^*}}{d_{b,k_b^*} - c_{b,k_b^*}})^{N_{b,k_b^*}}) \cdot \\
&\quad (1 - \frac{1}{2} \sum_{i=1, i \neq b}^m (\frac{d_{i,k_i^*} - c_{b,k_b^*}}{d_{b,k_b^*} - c_{b,k_b^*}})^{N_{b,k_b^*}})
\end{aligned}$$

By introducing α , $P(Q = Q_{b,k_b}^*)$ is greater than

$$\begin{aligned} & (1 - \frac{1}{2}(k_{max} - 1)\alpha^{N_{b,k_b}^*})(1 - \frac{1}{2}(m - 1)\alpha^{N_{b,k_b}^*}) \\ & \geq 1 - \frac{1}{2}(k_{max} + m - 2)\alpha^{N_{b,k_b}^*} \\ & \geq 1 - \frac{1}{2}(k_{max} + m - 2)\alpha^{\frac{T}{rmk_{max}}}. \end{aligned}$$

The theorem follows. $\square$

Given the total budgets T and a general cost function, i.e., without any assumption, the following theorem derives a lower bound of the solution obtained by *BARGS*.

Theorem 3. *The maximum group utility $E[Q]$ from the solution of BARGS is at least $N_{b,k_b^*}(\frac{1}{N_{b,k_b^*}+1})^{1+N_{b,k_b^*}^{-1}} \cdot Q^*$, where N_{b,k_b^*} after r stages is $\frac{4+mk_{max}(r-1)}{4rmk_{max}}T$, Q^* is the optimal solution for a PSGA problem in r -stage computational budget allocation, and k_b^* is the optimal group size of the best node v_b .*

Proof. It is challenging to derive the performance bound without any assumption on the cost function due to (1) no useful properties such as monotonicity, submodularity, and convexity, so it is impossible to estimate the performance according to the size, and (2) the cost function can dominate the performance bound or be neglected according to β . However, the cumulative distribution function of $Q_{i,k}^*$ follows the Gaussian distribution regardless to i and k . Therefore, we analyze the performance bound by regarding each combination of $Q_{i,k}^*$ as a sampling result of different start nodes.

Notice that, given a fixed size k , the maximum preference from the solution of *BARGS* from the best node v_b without the cost function is at least $N_b(\frac{1}{N_b+1})^{1+N_b^{-1}} \cdot Q^*$, where N_b after r stages is $\frac{4+m(r-1)}{4rm}T$, and Q^* is the optimal solution for a PSGA problem without cost function in r -stage computational budget allocation. Therefore,

$$E[Q] \geq N_{b,k_b^*}(\frac{1}{N_{b,k_b^*}+1})^{1+N_{b,k_b^*}^{-1}} \cdot Q^*, \quad (8)$$

If the computational budget allocation is r -stages with $T \geq k_{max}mr \frac{\ln(k_{max}m-1)}{\ln(\frac{1}{\alpha})}$, N_{b,k_b^*} is $\frac{T}{rmk_{max}} + \frac{1}{2} \frac{r-1}{2r}T$, which is $\frac{4+mk_{max}(r-1)}{4rmk_{max}}T$. The theorem follows. $\square$

Time Complexity of BARGS. The time complexity of *BARGS* contains two parts. The first phase selects m start nodes with $O(E + n + m \log n)$ time, where $O(E)$ is to sum up the interest and social tightness scores, $O(n + m \log n)$ is to build a heap and extract m nodes with the largest sum. Afterward, the second phase of *BARGS* includes r stages, and each stage allocates the computational resources with $O(m)$ time and generates $O(\frac{T}{r})$ new partial solutions with at most k_{max} nodes for all start nodes. Therefore, the time complexity of the second

phase is $O(r(m + \frac{T}{r}k_{max})) = O(k_{max}T)$, and *BARGS* therefore needs $O(E + m \log n + k_{max}T)$ running time.

4 Experimental Results

4.1 Experiment Setup

We implement *BARGS* in Facebook and invite 50 people from various communities, e.g., schools, government, technology companies, and businesses to join our user study. We compare the solution quality and running time of manual coordination and *BARGS* for answering PSGA problems, to evaluate the need of an automatic group recommendation service. Each user is asked to plan 5 social activities with the social graphs extracted from their social networks in Facebook. The interest scores follow the power-law distribution with the exponent as 2.5 according to the recent analysis [4] on real datasets. The social tightness score between two friends is derived according to the number of common friends, which represents the proximity interaction [2], and the probability of negative weights [10]. Then, the weighted coefficient λ on social tightness scores and interest scores and the weighted coefficient β on group preference and activity cost in Footnote 4 are set as the average value specified by the 50 people, i.e., $\lambda = 0.527$ and $\beta = 0.514$. Most importantly, after the scores are returned by the above renowned models, each user is allowed to fine-tune the two scores by themselves. In addition to the user study, three real datasets are evaluated in the experiment. The first dataset is crawled from Facebook with 90,269 users in the New Orleans network¹⁰. The second dataset is crawled from DBLP dataset with 511,163 nodes and 1,871,070 edges. The third dataset, Flickr¹¹, with 1,846,198 nodes and 22,613,981 edges, is also incorporated to demonstrate the scalability of the proposed algorithms.

In this paper, the activity cost is modelled by a piecewise linear function, which can approximate any non-decreasing functions. We set the activity cost according to the auditorium cost and other related cost in Duke Energy Center¹².

$$C(k) = \begin{cases} 400 - k & \text{if } 0 \leq k \leq 100. \\ 850 - k & \text{if } 100 < k \leq 600. \\ 2200 - k & \text{if } 600 < k \leq 1750. \end{cases}$$

We compare deterministic greedy (*DGreedy*), randomized greedy (*RGreedy*), and *BARGS* in an HP DL580 server with four Intel E7-4870 2.4 GHz CPUs and 128 GB RAM. *RGreedy* first chooses the same m start nodes as *BARGS*. At each iteration, *RGreedy* calculates the preference increment of adding a neighboring node v_j to the intermediate solution V_S obtained so far for each neighboring

¹² <http://www.dukeenergycenterraleigh.com/uploads/venues/rental/5-rateschedule.pdf>

Fig. 2. Results of user study

node, and sums them up as the total preference increment. Afterward, *RGreedy* sets the node selection probability of each neighbor as the ratio of the corresponding preference increment to the total preference increment, similar to the concept in the greedy algorithm. Notice that the computation budgets represent the number of generated solutions. With more computation budgets, *RGreedy* generates more solutions of group size k_{max} , examines the group utility by subtracting the activity cost from group size 1 to k_{max} , and selects the group with maximum group utility. It is worth noting that *RGreedy* is computationally intensive and not scalable to support a large group size because it is necessary to sum up the interest scores and social tightness scores during the selection of a node neighboring to each partial solution. Therefore, we can only present the results of *RGreedy* with small group sizes.

The default m in the experiment is set as n/k_{max} since n/k_{max} groups can be acquired from a network with n nodes if each group has k_{max} participants. The default cross-entropy parameters ρ and α are set as 0.3 and 0.99 as recommended by the cross-entropy method [13]. Since *BARGS* natively supports parallelization, we also implemented them with OpenMP for parallelization, to demonstrate the gain in parallelization with more CPU cores.

4.2 User Study

Figures 2(a)-(c) compare manual coordination and *BARGS* in the user study. In addition, the optimal solution is also derived with the enumeration method since the network size is very small. Figures 2(a) and (b) present the solution quality and execution time with different network sizes. The result indicates that the solutions obtained by *BARGS* are identical to the optimal solutions, but users are not able to acquire the optimal solutions even when $n = 5$. As n increases, the solution quality of manual coordination degrades rapidly. We also compare the accuracy of selecting the optimal group size in Figure 2(c). As n increases, it becomes more difficult for a user to correctly identify the optimal size, while *BARGS* can always select the optimal one. Therefore, it is desirable to deploy *BARGS* as an automatic group recommendation service, especially to address the need of a large group in a massive social network nowadays.

4.3 Performance Comparison and Sensitivity Analysis

Figure 3(a) compares the execution time of *DGreedy*, *RGreedy*, and *BARGS* by sampling different numbers of nodes from Facebook data. *DGreedy* is always the fastest one since it is a deterministic algorithm and generates only one final solution, whereas *RGreedy* requires more than 10^5 seconds. The results of *RGreedy*

Fig. 3. Experimental results on Facebook and DBLP datasets

do not return in 2 days as n increases to 10000. To evaluate the performance of *BARGS* with multi-threaded processing, Figure 3(b) shows that we can accelerate the processing speed to 7.2 times with 8 threads. The acceleration ratio is slightly lower than 8 because OpenMP forbids different threads to write at the same memory position at the same time. Therefore, it is expected that *BARGS* with parallelization is promising to be deployed as a value-added *cloud service*.

In addition to the running time, Figure 3(c) compares the solution quality of different approaches. The results indicate that *BARGS* outperforms *DGreedy* and *RGreedy*, especially under a large n . The group utility of *BARGS* is 45% better than the one from *DGreedy* when $n = 50000$. On the other hand, *RGreedy* outperforms *DGreedy* since it has a chance to jump out of the local optimal solution.

Figures 3(d) and (e) compare the execution time and solution quality of two randomized approaches under different total computational budgets, i.e., T . As T increases, the solution quality of *BARGS* increases faster than that of *RGreedy* because it can optimally allocate the computation resources. Even though the solution quality of *RGreedy* is closer to *BARGS* in some cases, *BARGS* is much faster than *RGreedy* by an order of 10^{-2} .

Figures 3(f) and (g) present the execution time and solution quality of *RGreedy* and *BARGS* with different numbers of start nodes, i.e., m . The results show that the solution quality in Figure 3(g) is almost the same as m increases, demonstrating that it is sufficient for m to be set as a value smaller than $\frac{n}{k_{max}}$ as recommended by OCBA [3]. The running time of *BARGS* for $m = 2$ is only

60% of the running time for $m = 4$ as shown in Figure 3(f), while the solution quality remains almost the same.

BARGS is also evaluated on the DBLP dataset. Figures 3(h) and (i) show that *BARGS* outperforms *DGreedy* by 50% and *RGreedy* by 26% in solution quality when $n = 500000$. *BARGS* is still faster than *RGreedy* by an order of 10^{-2} . However, *RGreedy* runs faster on the DBLP dataset than on the Facebook dataset, because the DBLP dataset is a sparser graph with an average node degree of 3.66. Therefore, the number of candidate nodes to be chosen during the expansion of the partial solution in the DBLP dataset increases much more slowly than in the Facebook dataset with an average node degree of 26.1. Nevertheless, *RGreedy* is still not able to generate a solution for a large network size n due to its unacceptable efficiency.

5 Conclusion

To the best of our knowledge, there is no real system or existing work in the literature that addresses the issues of scale-adaptive group optimization for social activity planning based on topic interest, social tightness, and activity cost. To fill this research gap and satisfy an important practical need, this paper formulated a new optimization problem called PSGA to derive a set of attendees and maximize the group utility. We proved that PSGA is NP-hard and devised a simple but effective randomized algorithms, namely *BARGS*, with a guaranteed performance bound. The user study demonstrated that the social groups obtained through the proposed algorithm implemented in Facebook significantly outperforms the manually configured solutions by users. This research result thus holds much promise to be profitably adopted in social networking websites as a value-added service.

Algorithm 1 BARGS

Input: Graph $G(V, E)$, social network size n , activity cost function $C(k)$, maximum group size k_{max} , correctly select probability $P(CS)$, solution quality Q , percentile of CE ρ , and smoothing weighting w

Output: The best group F generating maximum willingness

```

1:  $c_i = \infty, d_i = 0$  for all  $i$ ;
2:  $m = \lceil \frac{n}{k_{max}} \rceil, w = 0$ ;
